ABSTRACT

Time-series photometric observations were made for the SX Phoenicis star AE UMa between 2009 and 2012 at the Xinglong Station of National Astronomical Observatories of China. With the frequency analysis of the light curves, we confirmed the fundamental and the first overtone frequencies as $f_0 = 11.62560 \text{ c d}^{-1}$ and $f_1 = 15.03124 \text{ c d}^{-1}$. Additionally, we got 37 frequencies which are identified as the harmonics and the combinations of the fundamental and first overtone frequencies. 25 of which are newly detected. No frequencies of the other pulsation modes were found. The $O - C$ diagram, produced from 84 newly determined times of maximum light combined with those derived from the literature, reveals a continuous period variation with the rate of $(1/P_0)(dP_0/dt) = 5.4(8) \times 10^{-9} \text{ yr}^{-1}$ and $(1/P_1)(dP_1/dt) = -2.8(4) \times 10^{-8} \text{ yr}^{-1}$. Theoretical rates of period change due to the stellar evolution were calculated with the modeling code MESA. The result shows that the observed rate of period change is fully consistent with period change caused by the evolutionary behavior predicted by standard theoretical model. Constraint of the variation of P_1 allows us to determine the star's location on the H-R diagram precisely with the mass $1.72(\pm 0.06) M_\odot$ and the age $1.4(\pm 0.2) \times 10^9 \text{ yr}$.

1. INTRODUCTION

δ Scuti stars are a class of pulsating variable stars that lies in the classical instability strip crosses the main sequence on the Hertzsprung-Russell diagram, whose pulsations are driven by the κ –mechanism which drives both the Cepheids and the RR Lyrae stars as well. With masses between 1.5 and 2.5 $M_{\odot}$, periods between 0.03 and 0.3 *days*, luminosities between 10 and 50 $L_{\odot}$, these stars pulsate with amplitudes from mmag up to tenths of a magnitude.

The high-amplitude δ Scuti stars (hereafter HADS) are traditionally found to be slow rotators with one or two dominant radial modes with amplitudes larger than 0.1 mag, although they may occasionally have low-amplitude, non-radial modes in addition to the main pulsation modes (Poretti (2003)). It is interesting to probe whether it is an overall property of all HADS.

SX Phoenicis (SX Phe) stars, a subgroup of HADS, are old Pop. II stars. Because of the insufficient amount and the poor photometric precision of the observation data, whether any low-amplitude pulsations exist besides the dominant radial modes in most SX Phe stars are unknown. According to the existing data, they could probably be either in a post-giant branch stage of evolution or merged binary stars (Rodríguez & López-González (2000)). Although most SX Phe stars, which are characterized by high amplitudes of pulsation, low metallicity, and large spatial motion, are found to be members of globular clusters (Rodríguez & López-González (2000)), some of them have been discovered in the general star fields (Rodríguez & Breger (2001)). Particularly, pulsations in the majority of the field SX Phe variables display very simple frequency spectra with short periods ($\leq 0^{\text{d}}.08$) and large visual peak-to-peak amplitudes ($\geq 0^{\text{m}}.1$, c.f. Fu et al. (2008)). Precise time-series photometric observations reveal period changes in these stars, which should

¹Send offprint request to: jnfu@bnu.edu.cn

theoretically reflect the evolutionary changes in radius. Rodríguez et al. (1995) collected observed period changes found in some HADS (including SX Phe stars) and indicated that sudden jumps of period could be an explanation for the period changes observed in the SX Phe stars. Additionally, the study of period changes of double-mode SX Phe stars raises a further important question: how does the overtone frequency change? From a simple theoretical consideration, one could guess that the fundamental and overtone frequencies of radially pulsating SX Phe stars change in the same direction and at about the same rate. However, the star we study in this paper, AE UMa, has the fundamental and first overtone frequencies changed neither in the same direction nor at the same rate (Pócs & Szeidl (2001), Zhou (2001)). Therefore, it is interesting to investigate pulsation behaviors of this star with the extended data of improved photometric precision.

The star AE Ursae Majoris (hereafter AE UMa)(= HIP 47181, $\alpha_{2000} = 09^h36^m53^s$, $\delta_{2000} = 44^\circ04'01''$, $< V > = 11^m.27$, $P_0 = 0^d.0860$, $\Delta V = 0^m.10$, A9), was discovered by Geyer et al. (1955). The spectral type of AE UMa was classified by Götz & Wenzel (1961) as A9 in accordance with the type of variability. Until 1973, it was shown that the star had significant light-curve variation with the determination of the period of the light variation and the type of variability as dwarf Cepheid (Tsesevich (1973)). Then, the 1974 Konkoly observations found the beat phenomenon (Szeidl (1974)). In 1995, the star is listed as an SX Phe star in Garcia et al. (1995). However, Hintz et al. (1997a) showed strong evidence against this classification, and reclassified it as a normal Population I, high-amplitude δ Scuti star. According to the calculation of Breger & Pamyatnykh (1998), AE UMa had such fast period decreasing ($48 \times 10^{-8} \text{ yr}^{-1}$) only if it was a pre-MS star, but there exists no evidence that it is a pre-MS star. At last, both Pócs & Szeidl (2001) and Zhou (2001) analyzed pulsations of the star with better and longer data sets, and the results rejected the outcomes from Hintz et al. (1997a). AE UMa was classified as a Pop. II, post-MS SX Phe

star once again, with the fundamental frequency stable and the first overtone decreasing with a rate of about 10^{-8} yr^{-1} .

In the following sections, we present a detailed study of the period changes of AE UMa, mainly based on extended time-series CCD observations from 2009 to 2012 collected at the Xinglong Station of National Astronomical Observatories of China (NAOC). The organization of the paper is: Section 2 describes observations and data reduction; Section 3 introduces the pulsation analysis of the new data; Section 4 discusses the variations of the periods; Section 5 calculates the models with the constraints of the frequencies and their variations; Section 6 lists our conclusions.

2. OBSERVATIONS AND DATA REDUCTION

Photometric observations for AE UMa were made with the 85-cm telescope located at the Xinglong Station of NAOC between March 2009 and May 2012. The 85-cm telescope is equipped with a standard Johnson-Cousin-Bessel multicolour filter system and a PI1024 BFT CCD camera mounted on the primary focus ((Zhou et al. 2009)). The CCD camera has 1024×1024 pixels, corresponding to a field of view of $16.5' \times 16.5'$. Since March 2012, the CCD camera has been replaced by a PI512 BFT, which has 512×512 pixels corresponding to a field of view of $15' \times 15'$. The observations were made through a standard Johnson V filter with the exposure time ranging from 15 to 120 seconds, depending on the atmospheric conditions. A journal of the new observations is listed in Table 1.

In total, more than 17277 CCD frames of data were collected for AE UMa within 40 nights. Figure 1 shows an image of AE UMa taken with the 85-cm telescope, where the comparison star (TYC 2998-1249-1) and the check star (TYC 2998-1166-1) are marked.

CCD	Year	Month	Nights	Frames

	2012	Apr	5	556

Table 1: Journal of observations with the 85-cm telescope.

The coordinates and the brightness in V of the two stars are listed in Table 2. After bias, dark and flat-field corrections, aperture photometry was performed by using the DAOPHOT program of IRAF. The light curves were then produced by computing the magnitude differences between AE UMa and the comparison star. The standard deviations of the magnitude differences between the check star and the comparison star yielded an estimation of photometry precisions, with the typical value of $0^m.003$ in good observation conditions and $0^m.011$ in poor cases. Although there were slight zero-point shifts, we adjusted it with the fit light curves of the data for every month (assuming the frequencies are stable in a month).

Table 2: The comparison star and the check star used in the photometry of AE UMa

Star name	$\alpha(2000)$	$\delta(2000)$	V
Comparison = TYC 2998-1249-1	$09^h37^m28^s.5826$	$+44^\circ01'16''.854$	11.334
Check = TYC 2998-1166-1	$09^h37^m12^s.058$	$+43^\circ58'20''.12$	12.215

Table 2: Comparison and check stars

Fig. 1.— A CCD image ($16.5' \times 16.5'$) of AE UMa ($\alpha_{2000} = 09^{\text{h}}36^{\text{m}}53^{\text{s}}$, $\delta_{2000} = +44^{\circ}04'00''$) taken with the 85-cm telescope at the Xinglong Station. North is down and East is to the right. AE UMa, the comparison and the check star are marked.

Figure 2 shows the light curves of AE UMa in Johnson V band observed with the 85-cm telescope in 2009, 2010, 2011 and 2012, which was used to make frequency analysis.

3. PULSATION ANALYSIS

Frequency analysis was performed with the light curves of AE UMa in the years 2009, 2010, 2011 and 2012, respectively with the software PERIOD04 (Lenz & Breger (2005)), which makes Fourier transformations of the light curves to search for significant peaks in the amplitude spectra. Then, the light curves are fitted with the following formula

$$m = m_0 + \Sigma A_i \sin(2\pi(f_i t + \phi_i)). \quad (1)$$

In Table 3 was listed the solutions of up to 37 frequencies whose signal-to-noise ratios (S/N) are larger than 4.0 (Breger et al. (1993)). The solid curves in Figure 2 show the fits with the frequency solutions in different years. From Table 3, one notes that the 37 frequencies are composed of the fundamental and the first overtone frequencies, their harmonics and linear combinations. As can be noticed, no significant signals are detected in addition to these frequencies.

Figure 3 and Figure 4 show the window functions from 2009 to 2012 and the amplitude spectra of the frequency pre-whitening process for the light curves in V observed in 2009 with the 85-cm telescope at Xinglong station of NAOC respectively.

As can be seen from Figure 2, the constructed curves fit well the observed light curves collected in 2009, 2010, 2011 and 2012, which shows that the fundamental and the first overtone frequencies, their harmonics and linear combinations can explain the pulsation behavior of AE UMa.

To show the variations of frequencies and amplitudes of pulsations of the star, we compare our results with those from Zhou (2001). who collected data for AE UMa from

Fig. 2.— Light curves of AE UMa relative to the comparison star in the V band from 2009 to 2012, observed with the 85-cm telescope. The solid curves represent the fitting with a solution up to 18 frequencies listed in Table 3.

1974 to 2001. By dividing the data into four segments of datasets, Zhou (2001) analyzed the pulsations of AE UMa. In Table 4, we listed the pulsation parameters of the fundamental and first overtone frequencies of AE UMa we obtained with those from Zhou (2001).

Table 4: Frequencies and amplitudes of AE UMa for different segments of observations

Years	f_0	f_1	A_{f_0}	A_{f_1}
1974-1977	11.62557	15.03097	216.9	34.1
1981-1987	11.62290	15.07259	219.6	29.4
1996-1998	11.62560	15.03122	210.9	36.8
2000-2001	11.62561	15.03119	207.0	38.6
2009-2012	11.62560	15.03123	219.0	45.1
Mean	11.62506	15.03944	214.7	36.8
σ	0.001078	0.016575	4.9	5.2

Table 4: The pulsation parameters of AE UMa from 1974 to 2012 from our results for 2009-2012 and Zhou (2001) for 1974-2001.

From Table 4, one finds that both the amplitudes and the frequencies were subject only to small changes, during a time base of 38 years. Considering the precision of the historical data, we nearly cannot get more conclusion about the variation of the frequencies using this method. But for amplitude, we can see that A_0 is stable and A_1 increasing with slight rate during the last 30 years.

4. The $O - C$ Diagram

With the new observations from 2009 to 2012, the light curves around the maxima were fitted with a third polynomial, which is sufficient to derive times of maximum light. 84 times of maximum light in V band were determined.

In order to make the $O - C$ analysis for the period change of AE UMa, we combined the maximum times newly determined with those provided by Agerer et al. (1999a), Pócs & Szeidl (2001), Pejcha et al. (2001), Zhou (2001), Agerer & Hubscher (2003), Hubscher (2005), Hubscher et al. (2005), Klingenberg et al. (2006), Hubscher et al. (2006), Hubscher & Walter (2007), Samolyk (2010), Hubscher (2007), Hubscher et al. (2009), Hubscher et al. (2010) and Huebscher & Monninger (2011). In total, 462 times of maximum light were collected and listed in Table 5. However, due to the low precisions of the data observed with either the photograph (pg) and visuel (vis), we discarded those times of maximum light and used the left 444 data points to make the $O - C$ analysis. The used linear ephemeris formula is,

$$HJD_{max} = 2442062.5824 + 0^d.08601707E \quad (2)$$

, which is given by Pócs & Szeidl (2001). The $O - C$ values are listed in Table 5. The $O - C$ diagram is shown in Figure 5. A straight-line fit to the 444 times of light maxima yields the ephemeris formula,

$$HJD_{max} = 2442062.5818(0) + 0.086017078(1)E \quad (3)$$

, with a standard deviation of $\sigma = 0.0024(5)$ days.

Table 5. Times of Maximum Light and $O - C$ values of AE UMa. T_{max} is the observed times of maximum light in $HJD - 2400000$. E : Cycle number. $O - C$ is in days.

Det:detector. (pg=photograph, vis=visual, pe=photoelectric photometer.) S: source.

Points not used in the $O - C$ analysis are marked with asterisk.

According for the evolution-origin continuous changes of period of AE UMa, we obtained a forced quadratic solution by using a second-order polynomial fit,

$$HJD_{max} = 2442062.5821(6) + 0.086017060(1)E + 0.5 \times 1.1(8) \times 10^{-13}E^2 \quad (4)$$

, with the standard deviation of $\sigma = 0.0024(4)$ *days*. According to this fomula, one gets the period change rate of AE UMa as $(1/P_0)(dP_0/dt) = 5.4(8) \times 10^{-9} \text{ yr}^{-1}$, which is different from the result provided by Zhou (2001) of $-0.35 \times 10^{-10} \text{ yr}^{-1}$. Hence, the fundamental period is increasing other than decreasing.

Due to the star's double mode pulsation nature, the observed times of maximum light used in the above $O - C$ diagram analysis are not the times of maximum light of the fundamental period, but the result of the combination of the two modes. However, as the amplitude of the fundamental frequency is much larger than that of the first overtone frequency, we consider that that the period changes of P_0 we get is reliability.

As can be seen in Table 3, the sixth frequency is the modulation frequency $f_m = f_1 - f_0$, which modulates the amplitude of the light curves.

Since the modulation frequency f_m has not varied significantly (Pócs & Szeidl (2001)), one may take the method which used in Pócs & Szeidl (2001) and Zhou (2001) to calculate the rate of changes of the first overtone frequency. By replacing the period in Eq. (2) with the modulation period $P_m = 0^d.0293616$, the fit with the times of maximum light leads to the study of its secular changes. The ephemeris is,

$$HJD_{max}(P_m) = 2442062.5890(3) + 0.293615846(8)E \quad (5)$$

with a standard deviation of $\sigma = 0.0859$ *days*. A second-order polynomial fit gives,

$$HJD_{max}(P_m) = 2442062.5806(3) + 0.293617291(4)E - 0.5 \times 2.98(12) \times 10^{-11}E^2 \quad (6)$$

with a standard deviation of $\sigma = 0.0857$ *days*. Thus one can get the period change of f_m is

Table 5—Continued

$(1/P_m)(dP_m/dt) = -1.2(9) \times 10^{-7} \text{ yr}^{-1}$. From the relationship $f_1 = f_0 + f_m$, one derived

$$\frac{1}{P_1} \frac{dP_1}{dt} = P_1 \left(\frac{1}{P_m^2} \frac{dP_m}{dt} + \frac{1}{P_0^2} \frac{dP_0}{dt} \right). \quad (7)$$

Together with the value of $(1/dP_0)(dP_0/dt)$, one gets $(1/P_1)(dP_1/dt) = -2.8(4) \times 10^{-8} \text{ yr}^{-1}$. This value agrees with $-7.3 \times 10^{-8} \text{ yr}^{-1}$ derived by Pócs & Szeidl (2001) and $-4.3 \times 10^{-8} \text{ yr}^{-1}$ derived by Zhou (2001) in the order of magnitude.

5. CONSTRAINTS FROM THE THEORETICAL MODELS

5.1. Physical Parameters

Rodriguez et al. (1992) made *uvby* β photoelectric photometry for AE UMa. Intrinsic $b - y$, m_1 and c_1 values were derived and the physical parameters were determined. The effective temperature of AE UMa varied from $8130K$ at the light maximum to $7160K$ at the light minimum. When the secondary period is in phase with the fundamental period, the effective temperature can reach $8320K$. The surface gravity $\log g$ varied from 4.13 to 3.78. The mean values obtained along the cycle were $\langle T_{eff} \rangle = 7560K$ and $\langle \log g \rangle = 3.90$. The metal abundance was estimated from the δm_1 at the minimum light as $[Fe/H] = -0.3$. By using the $\log g - \log P$ relation derived by Claret et al. (1990), Rodriguez et al. (1992) obtained the values of $M = 1.80 M_\odot$, $Age = 1.3 \times 10^9 \text{ yr}$ and $M_{bol} = 1^m.76$. Hintz et al. (1997a) provided the value of $[Fe/H] = -0.1$ according to the relation between the P_1/P_0 ratio and the $[Fe/H]$ value for dwarf Cepheids which derived from Hintz et al. (1997b). They got the $[Fe/H]$ range from -0.4 to -0.1 . We listed the parameters of AE UMa from Rodriguez et al. (1992) and Hintz et al. (1997a) in Table 6.

Table 6: Physical parameters of AE UMa from Rodriguez et al. (1992) and Hintz et al. (1997a)

Parameters	Mean value	Intervals
$[Fe/H]$	-0.3	[-0.4,-0.1]
T_{eff}	7569	[7160,8320]
$\log g$	3.90	[3.78,4.16]
M_{bol}	—	[1.53,1.76]
M	—	[1.80,1.86]
$\log(L/L_{\odot})$	—	[1.196,1.288]
$\log T_{eff}$	—	[3.855,3.920]

Table 6: $\log(L/L_{\odot})$ value was derived base on $\log(L/L_{\odot}) = 0.4(M_{bol_{\odot}} - M_{bol})$.

5.2. Constraints from f_0 and f_1

Modules for Experiments in Stellar Astrophysics (MESA) is a suite of source-open, robust, efficient, thread-safe libraries for a wide range of applications in computational stellar astrophysics (Paxton et al. (2011, 2013)). A 1-D stellar evolution module, MESA star, combines many of the numerical and physics modules for simulations of a wide range of stellar evolution scenarios ranging from very-low mass to massive stars, including advanced evolutionary phases. The "astero" extension to MESA star implements an integrated approach that passes results automatically between MESA star and the new MESA module based on the adiabatic code ADIPLS (Christensen-Dalsgaard (2008)).

The κ module of MESA divides the opacity tables into a high-temperature domain, $\log(T/K) \geq 4$, and a low-temperature domain, $\log(T/K) \leq 4$. The exact range of $\log T$ over which the tables are blended can be adjusted at the runtime. Moreover, the κ module supports low- T opacities from either Ferguson et al. (2005) or Freedman et al. (2008) with updates to the molecular hydrogen pressure-induced opacity (Frommhold et al. (2010)) and the ammonia opacity (Yurchenko et al. (2011)). The electron conduction opacity tables,

based on Cassisi et al. (2007), have been expanded (Potekhin & Chabrier (2010)) to cover higher temperature (up to $10^{10} K$, originally $10^9 K$) and densities (up to $10^{11.5} g cm^{-3}$, originally $10^{9.75} g cm^{-3}$).

In the MESA version 4740, the astero extension enables calculation of selected pulsation frequencies by MESA star during the evolution of the model. This allows fitting to the observations that can include spectroscopic constraints (e.g., $[Fe/H]$ and T_{eff}), asteroseismic constraints, the large frequency separation ($\Delta\nu$) and the frequency of maximum power (ν_{max}), and even individual frequencies observed. For the automated χ^2 minimization, astero will evolve a pre-main sequence model from a user defined starting point, and find the best match along that single evolutionary track. The code then recalculates the track, again initiated at the pre-main sequence, with different initial parameters such as mass, composition, mixing length parameter and overshoot, and repeats until the lowest χ^2 has been found.

We used the scan-grid mode to minimize the χ^2 for each model, which helps to compact the intervals of the physical parameters. In all the calculations, the mixing-length parameter α_{MLT} was always chosen to be 1.89, since the choice has actually a very small effect on our models (Yang et al. (2012)). The convective overshooting parameter $f_{ov} = 0.015$ was the initial value of MESA. Table 7 lists the parameters of the grid of model to search for f_0 and f_1 of AE UMa.

The grid is shown in Table 7.

As the result, we got the models which included the frequencies f_0 and f_1 along with the stellar evolution tracks. Then, we chose the results whose $\chi^2 \leq 1$, and obtained the intervals of the parameters in Table 8.

One can see that the results were in agreement with the values in Rodriguez et al.

Table 7: The parameters of the grid of model to search for f_0 and f_1

Parameters	Maximum	Minimum	Step
$[Fe/H]$	-0.1	-0.4	0.05
initial Y	0.33	0.23	0.02
Mass	1.90	1.60	0.02

Table 7: The grid was constructed also within the parameter intervals of T_{eff} , $\log g$ and $\log(L/L_\odot)$ as listed in Table 6.

Table 8: The parameters determined with the constraints from f_0 and f_1

Parameters	Maximum	Minimum
$[Fe/H]$	-0.2	-0.4
initial Y	0.27	0.23
Mass	1.88	1.68

Table 8: The grid was constructed also within the parameters intervals of T_{eff} , $\log g$ and $\log(L/L_\odot)$ as listed in Table 6.

(1992), except the mass. With their observations and the method used, one can believe that the $[Fe/H]$ and the $\log g$ values were in great reliability (Strömberg (1956); Crawford & Mander (1966)). So, we decided to use the value $[Fe/H] = -0.3$ and $3.77 \leq \log g \leq 4.16$.

We used the formula

$$[Fe/H] = \log\left(\frac{Z}{X}\right) - \log\left(\frac{Z}{X}\right)_\odot \quad (8)$$

and the formula

$$X + Y + Z = 1 \quad (9)$$

to calculate the initial Z. In Girardi et al. (2000), the model was calculated with the couple of value $(Y, Z) = (0.25, 0.008)$, which accord with the values in our previous calculation (derived by MESA astero with the value of $[Fe/H]$).

At last, integrating all the information about the value of (Y, Z) , we decided to choose $(Y, Z) = (0.25, 0.008521)$ as the unique initial value for the subsequent calculation.

5.3. Constraints from the Period Variation

Not like the solar-like stars for which many frequencies are detected, HADS exits only one or two frequencies. As a result, the period variation becomes a very important constraint on the model calculation of these stars. Detection of high precision of period variation may offer strong constraints on AE UMa. It is interesting that AE UMa exits two frequencies with period variations in different scales and signs. But with the linear pulsation theory, variation of the period along with the stellar evolution should have values in the same sign and the same scale in most time. We used two different ways to calculate the period variations of AE UMa theoretically.

5.3.1. Calculation from Stellar Evolution Effect

The variation rate of the fundamental period derived from long intervals of observations of AE UMa shows a positive period change. From the theoretical point of view, the period changes caused by stellar evolution in and across the lower instability strip permit an observational test of stellar evolution theory (Breger & Pamyatnykh (1998)).

Assuming that the stellar mass $M = \text{constant}$ for the δ Scuti stars during the observation interval with mass of $1.68 - 1.88 M_{\odot}$ and that the variation of pulsation constant is negligible as a very small quantity, Breger & Pamyatnykh (1998) got

$$\frac{1}{P} \frac{dP}{dt} \approx -0.69 \frac{dM_{bol}}{dt} - \frac{3}{T_{eff}} \frac{dT_{eff}}{dt}. \quad (10)$$

where P is the period of a radial pulsation, M_{bol} is the bolometric absolute magnitude, T_{eff}

is the effective temperature.

As indicated by Rodríguez & Breger (2001), the SX Phe variables locate on or near the main sequence of the H-R diagram. Consequently, the evolutionary models are constructed from the pre-main-sequence Hayashi phase to the end of the post main sequence. As mentioned, the parameters we used are $(Y, Z) = (0.25, 0.008521)$, $\alpha_{MLT} = 1.89$ and $f_{ov} = 0.015$. In addition, we do not take the effect of rotation into account since AE UMa is a low-speed rotator.

The evolutionary tracks we constructed from $1.68 M_{\odot}$ to $1.88 M_{\odot}$ are shown in Figure 6, and the corresponding variation of the period were marked in the figure.

As shown in the Figure 6, the state which are consonant with the observed period change values derived from the $O - C$ analysis appear before the first turn-offs and after the second turn-offs on the evolutionary tracks when they leave the MS.

5.3.2. Calculaiton from ADIPLS

ADIPLS (the Aarhus adiabatic oscillation package) is a programme for calculation of adiabatic oscillations of stellar models (Christensen-Dalsgaard (2008)). We used it to calculate the frequencies of the model at each step of our evolutionary state. As a result, we got the frequencies of the model of f_0 and f_1 then deduced the variation of the frequencies of f_0 and f_1 . In the calculation, we assumed that f_0 and f_1 are the frequencies with $l = 0$ and $n = 1, 2$.

We calculated the evolutionary tracks from $1.68 M_{\odot}$ to $1.88 M_{\odot}$, getting the frequencies on each tracks, as shown in Figure 7.

In Figure 7, one can see that the models with appropriate frequencies for AE UMa

could appear (a) just before the first turn-offs, (b) after the first and before the second turn-offs, (c) just after the second turn-offs.

In addition, we also calculated the variation of the frequencies of the models using ADIPLS. The results are shown in Figure 8. It was not surprising that Figure 8 was in accord with Figure 6, which showed also the variation of the fundamental frequency.

In Figure 9, we show the models with variation of the first overtone frequency f_1 in accord with the observed values. For the adiabaticity of the code ADIPLS, we get the variation of f_1 almost as that of f_0 , with the same scale and the sign, even though they may not be equal to each other exactly in every points.

The $\log(L/L_\odot)$ values from literatures have a low reliability, but the $\log g$ values have a high reliability are not sensitive to the evolutionary effect. As a result, we show the figures both of them ($\log(L/L_\odot)$ vs $\log T_{eff}$, $\log g$ vs $\log T_{eff}$).

Integrating the results of calculation of the frequencies and the variation of frequencies and comparison with the observed values, we can conclude that AE UMa should locate on either before the first turn-offs or after the second turn-offs of the evolutionary tracks leaving the MS.

We assume that AE UMa is a regular radial pulsator with two frequencies. The variation of the fundamental frequency of AE UMa is caused by the evolutionary effect. The rate of the variation is consistant with the theoretically predicted values by Breger & Pamyatnykh (1998).

On the other hand, we would discuss the variation of the first overtone period which puts another constraint on the models. But once we put these constraints (f_0 , f_1 , $(1/P_0)(dP_0/dt)$ and $(1/P_1)(dP_1/dt)$) together, we cannot find any overlap on the evolutionary tracks (superimposing Figure 7, Figure 8 and Figure 9). Considering with the

adiabaticity of ADIPLS, we can just obtain the different pulsation modes’ period changes with same signs and scales.

As we know, the evolutionary effect is originated from the core nuclear reaction, and propagate from inner to outer of the stellar. So we can conclude the evolution of the exterior is later than it of interior. In the theory of stellar pulsation, the domain of fundamental mode pulsation is deeper (more close to the core) than first overtone mode pulsation. Or we can say that the fundamental mode is more sensitive than the first overtone mode to the effect of evolution.

Hence, when the evolution state of the interior of the star pass through the second turn-off on the tracks (Figure 8), the exterior of the star is still in the state between the two turn-offs and preparing to pass through the second turn-off.

With the discussion above, one can explain the different signs of the period changes of the two pulsation modes, and conclude that AE UMa is located just after the second turn-off on the evolutionary tracks (see Figure 8 and Figure 9). Its corresponding mass ranges from $1.68 M_{\odot}$ to $1.80 M_{\odot}$, age from $1.23 \times 10^9 \text{ yr}$ to $1.51 \times 10^9 \text{ yr}$.

6. CONCLUSIONS

With the photometric observation data from 2009 to 2012 obtained at Xionglong Station of NAOC, we analyed the pulsations of AE UMa and resolved up to 37 frequencies, 25 of which are newly detected. All these frequencies are shown to be harmonics or combinations of the two main frequencies $f_0 = 11.62560 \text{ c d}^{-1}$ and $f_1 = 15.03123 \text{ c d}^{-1}$, corresponding to the fundamental and the first overtone modes.

A new $O - C$ diagram was constructed with the 84 times of maximum light determined from our new observations and those listed in the literature, leading to the updated value of

period $P_0 = 0.0860170781$ *days*. The new ephemeris with a quadratic solution suggests that the fundamental period change rate of AE UMa $(1/P_0)(dP_0/dt) = 5.4(8) \times 10^{-9} \text{ yr}^{-1}$ and the first overtone period change with a rate of $(1/P_1)(dP_1/dt) = -2.84 \times 10^{-8} \text{ yr}^{-1}$. The first value is different from the result obtained by Zhou (2001), but the second is consistent with the value obtained by Pócs & Szeidl (2001) and Zhou (2001).

We calculated models of stars with masses between $1.68 M_\odot$ and $1.88 M_\odot$. With the constraints of the values of f_0 , f_1 , $(1/P_0)(dP_0/dt)$ and $(1/P_1)(dP_1/dt)$, we concluded that AE UMa locate near the second turn-off of the post-MS evolution tracks with the mass $1.72(\pm 0.06) M_\odot$ and the age $1.4(\pm 0.2) \times 10^9 \text{ yr}$. The results of our calculation support the hypothesis that the period variations derived from the observations are mainly a result of the stellar evolution.

More precise spectroscopic observations are needed, with which one can get more accurate values of T_{eff} and $\log g$, and stronger constraints on the stellar models. As a result, one can study details of the evolutionary effect propagating from the inner to the outer layer of the star.
